INTRODUCTION

Cervical radiculopathy (CR) is a common diagnosis associated with neck pain that extends to the arm and is accompanied by signs of nerve root compression upon physical examination. CR is commonly called a “pinched nerve” because the nerve in the neck is compressed or irritated resulting in shoulder pain, muscle weakness, and arm to hand numbness. The annual incidence rate of CR is 83 cases per 100,000 individuals; the incidence increases after 50 years of age (203 cases per 100,000 individuals). The onset of CR is usually caused by cervical disc pathology or another space-occupying lesion that causes nerve root irritation. The pathology underlying CR commonly includes a reduction in the size of the intervertebral foramen due to irritation and/or degenerative changes. This reduction in the size of the intervertebral foramen can result in neural inflammation, edema, hypoxia, ischemia, fibrosis, constrained gliding movement, and expanded mechanosensitivity. Patients may have radicular pain, paresthesia, or motor findings, such as muscle weakness in the dermatomal or myotomal pattern of an affected nerve root. There appears to be general agreement that the C6 and C7 vertebrae of the cervical spine are the most frequently involved nerve roots. Range of motion can be restricted, causing impairment in patients with CR. Although the causes of CR have been established, the mechanism that generates radicular pain is not completely understood. Manual interventions have been proposed not only to restore the normal function of the affected nerves and body parts but also to reduce/eliminate the pain and disability caused by CR.

The symptoms of CR vary depending on the involved nerve root. Although patients with CR may experience episodes of neck pain, but arm pain is the most common reason for seeking treatment. Patients are generally presented with pain, shivering, numbness, and weakness in the upper extremity, which frequently cause substantial functional restrictions and disability. Patients with both neck and upper extremity symptoms reportedly have more prominent functional restriction and disability than patients with only neck pain.

Magnetic resonance imaging and electrophysiological tests are often used to diagnose CR. Utilizing electrodiagnostic testing data as a gold standard, a clinical prediction rule was established to distinguish the level of CR using a restricted subset of variables from the clinical examination. The rates of surgical intervention for CR (e.g., anterior cervical discectomy and fusion, artificial disk replacement, and posterior cervical laminoforaminotomy) and degenerative conditions have
increased steadily over the past decade; however, such interventions are associated with increased expense and risk of complications, highlighting the need to determine the best non-operative management strategies. One study reported that 26% of individuals who underwent surgery continued to experience pain at follow-up after 1 year. Research suggests that patients who were treated conservatively showed better results than patients undergoing surgical treatment. In 75% of cases, treatment was conservative and focused on rehabilitation. The rehabilitation programs are generally multifaceted with a variety of physical techniques, none of which have ensured efficacy. A large number of physical therapy interventions have been proposed for managing CR, including traction, postural training, exercise, and manual therapy of the cervical and thoracic spine.

Physical therapists often use traction to treat CR. The assessment of the application techniques and clinical results of traction shows a discrepancy. Cervical traction comprises of controlling a diverting force in the Y-axis to the neck to distract the cervical segments, enlarge the intervertebral foramen, and reduce the intradiscal pressure in an attempt to ease the mechanical irritation of the nerve root caused by the intervertebral discs. Treatment can be applied intermittently or continuously. Traction may prevent or reduce attachments/adhesions inside the dural sleeve, and can ease nerve root compression inside the central foramina. The research confirms that traction reduces pressure inside the vertebral discs, and unloads the spine's structures by extending the muscles and ligaments. Additional physical therapy treatments are often applied as part of CR management, although it is not clear which treatment is the most effective.

**METHODS**

The present review was conducted by searching through the following databases: Cochrane Database of Systematic Reviews, Cochrane Central Register of Controlled Trials, MEDLINE with Full Text, Cochrane Methodology Register, and SPORTDiscus with Full Text. The following key terms were used to search articles regarding the systematic review: “arm pain,” “cervical intermittent traction,” “cervical radiculopathy,” “cervical traction,” “intermittent mechanical traction,” “mechanical traction,” “manual therapy,” “neck pain,” and “physical therapy.” All studies dated from 2000 to 2016 were included in the search process.

The papers were selected for study inclusion based on the following criteria: (a) the full text of the studies were available in English, (b) the presented patients were diagnosed with “cervical radiculopathy,” (c) the patients used “intermittent mechanical traction” as an intervention method, (d) the studies were published within the year 2000–2016, and (e) the papers provided statistical analyses and all relevant statistics helpful to evaluate the effectiveness of IMT in treating CR.

The extracted information included the publication details, study design, intervention protocol, outcome measures, patient sample, and statistical results. According to the Cochrane Back Review Group’s recommendations, a risk of bias assessment form was used to assess the quality of the studies. Two independent reviewers (GJG and JMM) evaluated the following aspects: randomization, allocation concealment, participant blinding, personnel blinding, assess or blinding, drop-out rate, the method of dealing with missing data, selective outcome reporting, similarity at baseline, co-intervention, compliance, and the timing of the outcome. Figure 1 presents the selection process.

The best evidence synthesis approach, GRADE, was used to assess the quality of evidence because the heterogeneity of the participants, interventions, and outcomes indicated that a meta-analysis was not applicable. GRADE addresses many of the perceived shortcomings of existing models of evidence evaluation. Specifically, GRADE focuses on assessing: (a) methodological flaws within component studies, (b) consistency of results across different studies, (c) generalizability of research results to the wider patient base, and (d) how effective the treatments have been shown to be. Two independent reviewers (GJG and JMM) evaluated the quality and validity of the studies. The following factors lowered the level of evidence: (1) study design (downgraded when >25% of the participants were from studies with a high risk of bias); (2) within-study risk of bias; (3) consistency of the results (downgraded when statistical heterogeneity [I² > 40%] or findings were inconsistent [defined as <75% of the participants reporting findings in the same direction]); (4) precision (downgraded when the total number of participants across studies was <300 for each outcome); and (5) reporting bias. The following factors increased the level of evidence: (1) a large magnitude of effect; (2) confounding that reduced a demonstrated effect; and (3) a high dose-response gradient.

Four levels of evidence exist in the GRADE approach:

- **Level 1**: Evidence from at least 1 randomized controlled trial (RCT) with low risk of bias.
- **Level 2**: Evidence from at least 1 RCT with high risk of bias, multiple small RCTs, or more than 1 RCT, where the results are consistent.
- **Level 3**: Evidence from non-RCTs, or RCTs with conflicting results.
- **Level 4**: Evidence from expert committee reports or opinions or case series or reports of cohort studies.

**Fig. 1 Selection process.**
(1) **High quality**: Further research is highly unlikely to change the confidence in the estimate of effect.

(2) **Moderate quality**: Further research is likely to have a significant effect on the confidence in the estimate of effect that may lead to change in the estimate.

(3) **Low quality**: Further research is likely to have a significant effect on the confidence in the estimate of effect, and may probably lead to change in the estimate.

(4) **Very low quality**: We are very uncertain about the estimate.

### RESULTS

The described database search yielded 27 papers; nine met the specified inclusion criteria. Table 1 summarizes objective characteristics of each paper.

The study participants from the included nine studies were recruited from either physical therapy clinics or hospitals across different locations including Turkey, United States, Greece, Tunisia, and Iran. In total, 393 patients were analyzed from the nine studies. The participants were older than 18 years of age with the mean age of 34.32 years old. All studies included IMT as the principal intervention method while some also included other interventions in combination with IMT (Table 2). The considerable variation of follow-up periods, outcome measures, levels of traction intensity, and intervention frequencies in the included studies limited the author’s ability to pool the data.

Independent reviewers reached agreement about the risk of bias assessment for the included studies (Table 3). Any differences that occurred between reviewers were resolved based on risk of assessment categories. The risk of bias was determined according to how each study adhered to the 12 points used to assess the risk of bias. These 12 points include: randomization, allocation concealment, patient blinding, care provider blinding, outcome assessor blinding, acceptability of dropouts, intention to treat, selective outcome reporting, similarity of groups at baseline, avoidance and similarities of co-interventions, compliance, and timing of outcome assessment. The risk of bias was assessed according to how each of the study adhered to the aforementioned 12 points. Therefore, a study was considered to have low risk of bias if the number of points it adhered positively is higher than six (half of the total) whereas a study was considered to have high risk of bias if the number of points it adhered positively is lower than six. As a result, only two studies were considered to have low risk of bias and the rest were considered to have high risk of bias.

Table 4 describes the interventions used in the included studies and the application of the GRADE method to assess the studies’ overall level of evidence, which ranged from moderate to low and very low.

A meta-analysis of the different conservative treatments was not possible because of the differences in the participants, interventions, and outcomes. However, taking each study individually and comparing it to somewhat similar studies can still generate valuable insights. Two of the studies examined the effect of physiotherapy exercises and IMT. One of those studies had a high risk of bias and a low level of evidence; the study observed that 10 of 11 patients with CR who underwent IMT exhibited reduced pain and improved function at 6-month follow-up. While the other study conducted by Albayrak Aydin and Yazicioglu that had a low risk of bias provided a statistical analysis demonstrating that physical therapy and exercise led to reduced pain at 3 weeks of follow-up (VAS: 44.62 ± 15.6 and MGS: 4.79 ± 5.12; p = 0.037; p = 0.042, respectively). The authors concluded that traction with regular physiotherapy modalities (e.g., hotpack, ultrasound, and TENS) accompanied by home exercises for 3 weeks increased hand-grip strength on the affected arm and reduced neck and arm pain substantially in C7 radiculopathy due to herniated disc.

Two other studies have examined the effect of intermittent traction vs. a continuous traction. Both studies conducted RCTs with a total of 86 patients. The results of both studies revealed that mechanical traction significantly reduced the neck and arm pain, improved nerve function, and increased neck mobility as compared to continuous traction.

Three studies have examined the effect of cervical traction. All three studies conducted nonrandomized trials with a total of 20 patients. Constantoyannis et al. concluded that cervical spine traction could be considered as a therapy of choice for radiculopathy caused by herniated disks, even in cases of large-volume herniated disks.
Effectiveness of intermittent mechanical traction in cervical radiculopathy: a systematic review

8,9 - 45

Moeti and Marchetti9 reported that NDI, when used in conjunction with the NPRS, provides a more comprehensive assessment of patients with CR, thus allowing clinicians to make better judgments about the clinical effects of cervical traction. Meanwhile, Savva and Giakas6 found that cervical traction combined with neural mobilization could significantly reduce pain and disability in CR. All these three studies clearly established the effectiveness of cervical traction in reducing pain and disability in CR. Frit et al.1 examined the effectiveness of cervical traction plus exercise for specific subgroups of patients with neck pain. A total of 86 patients were collected using RCT. These participants were divided into three groups and were measured at three times: 4 weeks, 6 weeks, and after 1 year. The results revealed that adding mechanical traction to patients for CR reduced disability and pain, particularly at long-term follow-up. Lastly, Young et al.5 examined the effects of manual therapy and exercise with or without cervical traction on pain, function, and disability in patients with CR. A total of 81 patients were collected using RCT. The participants were divided into two groups and were measured at 2 and 4 weeks after the interventions. The authors reported that there is no significant differences existed between the groups for any of the primary or secondary outcomes at 2 or 4 weeks.

DISCUSSION

From the systematic review of studies assessing the effectiveness of IMT in treating CR, it cannot be concluded firmly that a difference in the effect existed between the physical therapy combined with exercise, and the addition of IMT. Particularly, only two out of the nine studies revealed that IMT with physical therapy do significantly reduce pain and disability in CR. However, almost all studies except one, concluded that tractions are better than other interventions. That is, providing tractions result to significant decrease in pain, increase in mobility, and improve in nerve function. Furthermore, what can be inferred from Tables 3 and 4 is that studies with a very low level of evidence and a high risk of bias examined only the effect of IMT,6,9 and another study with a high risk of bias and a very low level of evidence combined IMT with the neutral mobilization of pain.5 These three studies included a total of 20 participants. The studies favored IMT as a treatment for CR, but their lack of evidence and high risk of bias prevented the authors from concluding IMT being the best treatment approach.

Two of the studies that compared continuous and intermittent traction provided very low-level evidence on the ineffectiveness of intermittent traction over continuous traction used against pain. The authors of these studies stated that the manual or mechanical cervical traction appeared to contribute significantly towards the rehabilitation of CR that may considerably reduce the neck and arm pain.4,7

Another study with a high risk of bias examined manual therapy combined with exercise and intermittent cervical traction. The primary outcomes’ effect size was small (Neck Disability Index (NDI)1, 1.5, 95% CI = −6.8 to 3.8; PSFS = 0.29, 95% CI = −1.8 to 1.2; and NPRS = 0.52, 95% CI = −1.8 to 1.2), resulting in very low-level evidence with no significant effect on pain or disability.5

The recent study by Fritz et al.1 with a low risk of bias and a moderate level of evidence examined the effects of exercise combined with IMT compared with only exercise and over-door mechanical traction. The results of the intention-to-treat analyses for the primary outcome indicated lower NDI scores for the mechanical traction group at 6-month follow-up (mean difference compared with the exercise group, 13.3; 95% CI: 5.6, 21.0; mean difference compared with the over-door traction group, 8.1; 95% CI: 0.8, 15.3). The study concluded that including IMT to a standard exercise program for patients with CR resulted in lower disability and pain intensity ratings at long-term follow-up. Fritz et al. stated that the effectiveness of IMT may be enhanced when it is provided in conjunction with an exercise program.

Overall, very low-level evidence from three other studies indicated that IMT was effective in the patients with CR.1,5,9 No effect sizes for pain and disability were pooled from these studies; they were insignificant and clinically irrelevant. One of the low-risk-of-bias study indicated that at 3-weeks of follow-up, IMT was more effective in relieving neck pain and disability than physical therapy and exercise.5 One of the studies with a very low level of evidence and high risk of bias reported no significant effects on pain or disability.5

CONCLUSIONS

The aim of this study was to evaluate evidence to determine if IMT is an effective treatment for CR. A systematic review revealed differences in the methodologies of the included studies. Contradictory results regarding the effect of IMT were also noted. Nine studies tested the intervention; four had a very low level of evidence, four had a low level of evidence, and one had a moderate level of evidence. Seven studies were determined to have a high risk of bias; two had a low risk of bias. The literature with a moderate level of evidence and a low risk of bias indicated that IMT reduced the disability and pain scores, suggesting that the treatment has a positive effect on patients with CR. Future research should be conducted focusing on the development of new randomized clinical trials with a low risk of bias and high-quality evidence that include larger sample sizes, and compare the effectiveness of conservative interventions and IMT to provide more adequate results.

LIST OF ABBREVIATIONS
Intermittent Mechanical Traction (IMT), Cervical Radiculopathy (CR), Grading of Recommendations, Assessment, Development and Evaluation method (GRADE), Neck Disability Index (NDI), Randomized Clinical Trial (RCT), Numeric Pain Rating Scale (NPRS)

PERSPECTIVE
This article analyzes the strength of evidence and risk of bias in the current literature regarding the treatment of cervical radiculopathy (CR) by using intermittent mechanical traction. This analysis may help the practicing clinicians to quickly assess multiple studies and decide at a conclusion regarding the use of CR.
