Cellular Senescence Is Induced by the Environmental Neurotoxin Paraquat and Contributes to Neuropathology Linked to Parkinson’s Disease

Graphical Abstract

Highlights

- Postmortem PD brain samples display increased astrocytic senescence
- Cultured human astrocytes exposed to paraquat (PQ) become senescent
- Clearance of senescent cells mitigates neurodegeneration in a mouse model of PD
- Senescent astrocytes may contribute to the development of sporadic PD

In Brief

Chinta et al. argue that eliminating senescent cells could hold therapeutic promise for halting progression of sporadic PD, where environmental exposure is a major risk factor. They find that senescence cell depletion abrogates development of neurodegenerative phenotypes associated with systemic PQ exposure, indicating that senescent cells can contribute to neurodegeneration.
Cellular Senescence Is Induced by the Environmental Neurotoxin Paraquat and Contributes to Neuropathology Linked to Parkinson’s Disease

SUMMARY

Exposure to the herbicide paraquat (PQ) is associated with an increased risk of idiopathic Parkinson’s disease (PD). Therapies based on PQ’s presumed mechanisms of action have not, however, yielded effective disease therapies. Cellular senescence is an anticancer mechanism that arrests proliferation of replication-competent cells and results in a pro-inflammatory senescence-associated secretory phenotype (SASP) capable of damaging neighboring tissues. Here, we demonstrate that senescent cell markers are preferentially present within astrocytes in PD brain tissues. Additionally, PQ was found to induce astrocytic senescence and an SASP in vitro and in vivo, and senescent cell depletion in the latter protects against PQ-induced neuropathology. Our data suggest that exposure to certain environmental toxins promotes accumulation of senescent cells in the aging brain, which can contribute to dopaminergic neurodegeneration. Therapies that target senescent cells may constitute a strategy for treatment of sporadic PD, for which environmental exposure is a major risk factor.

INTRODUCTION

Although genetic mutations that result in the development of familial Parkinson’s disease (PD) have been identified, these account for a minority of disease cases. The majority of cases are sporadic in nature and likely involve the contribution of various environmental exposures over the course of the lifespan (Wirdefeldt et al., 2011). A better understanding of the mechanisms involved in the contribution of these factors to neuropathology is a vital missing piece of the puzzle that will help unravel the underlying causes of idiopathic disease. Exposure to the herbicide paraquat (PQ) is strongly associated with increased lifetime risk for the development of sporadic PD. Its systemic administration in mice results in several hallmark neuropathological features of the disorder. However, therapies based on the agent’s presumed mechanisms of action have yet to yield effective disease therapies (Le et al., 2014; Wirdefeldt et al., 2011). Preventive and therapeutic treatments for idiopathic PD may require uncovering of disease mechanisms and targets distinct from those identified to date.

We report the contribution of a factor thought to contribute to aging in many tissues: cellular senescence (Campisi, 2013; Chinta et al., 2013, 2015; Salminen et al., 2011). Cellular senescence is an anticancer mechanism occurring in cells capable of division, and it results in irreversible arrest of cell proliferation in response to stress that puts cells at risk for malignant transformation (Campisi, 2013; Prieur and Peeper, 2008). Senescent cells express a senescence-associated secretory phenotype (SASP)—the robust secretion of numerous inflammatory cytokines, chemokines, growth factors, and proteases (Coppé et al., 2008). Senescent cells accumulate with age in many human and mouse tissues. There, presumably by virtue of the SASP, they have been shown to contribute to the age-related loss of tissue structure and function (Baker et al., 2016; Campisi, 2013; Dimri et al., 1995; Muñoz-Espín and Serrano, 2014; van Deursen, 2014). Cellular senescence may be an example of evolutionary antagonistic pleiotropy—protecting organisms from cancer early in life but driving aging phenotypes at advanced age.

Although senescent cells have been demonstrated to contribute to age-related pathologies outside the brain, evidence to date for their contribution to age-related neurodegenerative diseases is only correlative (Bhat et al., 2012; Chinta et al., 2015; Mombach et al., 2015; Salminen et al., 2011; Tumquist et al., 2016). Here, we report that postmortem tissue from sporadic PD patients displays increased expression of senescent markers, particularly within astrocytes. PQ is also able to induce senescence in cultured human astrocytes and in vivo. Significantly, inducible depletion of in vivo senescence reduces...
the development of neurodegenerative phenotypes associated with systemic PQ exposure, demonstrating that senescent cells contribute to neurodegeneration in an in vivo neurodegenerative disease model. Our data suggest that strategies aimed at eliminating senescent cells hold promise as potential therapies to mitigate the development of sporadic PD, for which environmental stress is a major contributing factor.

RESULTS

Senescent Astrocytes and SASP Factors Are Elevated in Parkinsonian Substantia Nigra Pars Compacta

Astrocytes expressing senescence markers increase in human brain tissue during normal aging (Kang et al., 2015) and further in affected brain regions of individuals with Alzheimer’s disease (AD) and amyotrophic lateral sclerosis (ALS) (Bhat et al., 2012; Turnquist et al., 2016), prompting us to ask whether senescent astrocytes are present in PD (Figures 1A and 1B). Compared to control tissues, Parkinsonian SNpc tissues displayed elevated expression of the senescence marker p16(INK4a), and several SASP factors including the protease MMP-3 and the pro-inflammatory cytokines interleukin-6 (IL-6), IL-1α, and IL-8 (Figure 1A). Elevated p16(INK4a) and MMP-3 expression has also been reported in cortical tissue from AD patients (Bhat et al., 2012).

We next determined whether SNpc astrocytes in particular display evidence of cellular senescence in PD tissues. A reduced nuclear level of lamin B1, detectable by immunostaining in intact tissue, is an established senescence-associated marker (Freund et al., 2012). Astrocytes (GFAP+ cells) were found to be lamin B1 deficient in PD SNpc tissues while no significant difference was detected in PD versus aged-matched control tissues in non-astrocytic (GFAP−) neighboring cells (Figures 1B and S1). These findings suggest the elevated presence of senescence in affected PD tissues and that astrocytes may preferentially undergo senescence in diseased brain tissues.

PQ induces Senescence and an SASP in Human iPSC-Derived Astrocytes

We next assessed the ability of human astrocytes derived from induced pluripotent stem cells (iPSCs) to undergo senescence in response to PQ, an environmental insult significantly associated with PD (Pezzoli and Cereda, 2013). In adult mice, chronic, low-dose systemic exposure to PQ recapitulates several important hallmarks of the disease, including selective loss of dopaminergic (DAergic) SNpc neurons and reduced motor function (McCormack and Di Monte, 2003; Pezzoli and Cereda, 2013; Tanner et al., 2011). Cultured human astrocytes exposed to PQ ceased proliferation based on decreased percentage of bromodeoxyuridine (BrdU)-labeled cells (Figure 2A). They also displayed several additional hallmarks of senescence, including increased senescence-associated β-galactosidase (SA-β-gal) activity (Dimri et al., 1995) (Figure 2B), increased levels of p16INK4a (Beauséjour et al., 2003) mRNA and protein (Figures 2C and 2D), and increased numbers of SA-β-gal+ foci, the latter indicative of DNA-damage signaling, which is a potent stimulator of the SASP (Beauséjour et al., 2003) (Figure 2E). Consistent with development of an SASP, PQ also induced robust secretion of the pro-inflammatory cytokine IL-6 (Figure 2F), a prominent component of the SASP (Coppé et al., 2008).

Given that genotoxic stress induced by ionizing radiation (IR) initiates senescence with well-documented effects on mitosis and nuclear size (Pospelova et al., 2013), we verified that compared to IR, PQ caused a similar decrease in the percentage of Ki67+ cells (Figure 3A) and an increase in the mean size of astrocyte nuclei (Figure 3B). Human fibroblasts cultured with PQ for 24 hr also displayed these phenotypes as well as decreased Lamin B1 levels and increased SA-β-gal activity (Figures 3A–3D). These data indicate that PQ is capable of inducing senescence in human astrocytes as well as human fibroblasts (Jung et al., 2009). However, astrocytes were more sensitive than fibroblasts to PQ-induced senescence based on SA-β-gal activity. Interestingly, a concentration of PQ that induced...
Figure 2. PQ Induces Senescent Phenotypes in Cultured Human Astrocytes

Cultured human astrocytes were treated with 100 or 250 μM PQ (or vehicle) for 24 hr, and senescence markers were evaluated 7 days later.

(A) Representative images of BrdU labeling (left), and percentage of BrdU+ cells (right).

(B) Representative images of SA-β-gal activity (left), and percentage of SA-β-gal+ cells (right).

(C) qPCR of p16INK4a mRNA levels.

(D) Representative images of immunostaining for p16INK4a (left), and percentage of p16INK4a-positive cells (right).

(E) Representative images of 53BP1 immunostaining (left), and percentage of cells with >1 53BP1 positive foci (right). Nuclei were counterstained with DAPI (blue) and white arrows denote enlarged cells shown in insets with punctate nuclear foci.

(F) Secreted IL-6 levels measured by ELISA in conditioned media from non-senescent (vehicle) and senescent (PQ) astrocytes.

For (A)–(D), n = 4, where n = experimental replicates; *p < 0.05, **p < 0.01, and ***p < 0.005 (unpaired t test).
Figure 3. Paraquat Induces Morphological Features of Senescence and Arrests Proliferation in Both Fibroblasts and Astrocytes

(A) Human fibroblasts (top panels) and human astrocytes (bottom panels) respond to PQ (1 mM and 300 μM, respectively) by decreasing the percentage of Ki67+ cells (green) compared to vehicle-treated controls. Representative images (left) and quantification (right) are shown. The decreased percentage of Ki67+ cells is similar to the decrease observed when cells are exposed to 10 Gy X-ray (IR, middle panels). For fibroblasts, both IR and 1 mM PQ significantly reduced Ki67 positivity; ***p < 0.0001 (1 mM PQ was not significantly different from IR [p > 0.07]; unpaired t test); n = 4 experiments. For astrocytes, IR and 300 μM PQ significantly reduced Ki67 positivity; **p < 0.01 (300 μM PQ was not significantly different from IR [p > 0.8]; unpaired t test); n = 2 experiments.

(B) Human fibroblasts (top) and human astrocytes (bottom) respond to PQ with a significant increase in nuclear size compared to vehicle-treated controls. Representative images (left) and quantification (right) are shown. Increased nuclear size is similar to the increase obtained with IR exposure. For fibroblasts both conditions (IR and 1 mM PQ) are significantly greater than control; ***p < 0.0001 (1 mM PQ is not significantly different from IR [p > 0.30]; unpaired t test); n = 6 experiments. For astrocytes, both conditions (IR; 300 μM PQ) are significantly greater than control; *p < 0.02 (300 μM PQ is not significantly different from IR [p > 0.5]; unpaired t test); n = 5 experiments.

(C) Human fibroblasts respond to PQ (500 μM and 1 mM) with a significant loss of lamin B1 staining in the nuclear lamina relative to vehicle-treated controls. Representative images (left) and quantification (right) are shown. Decreased lamin B1 staining is similar to that obtained with IR. All conditions (IR; 500 μM and 1 mM PQ) are significantly different from control; **p < 0.01 (neither PQ condition differed significantly from IR [p > 0.25]; unpaired t test); n = 2 experiments.

(D) Human fibroblasts (1 mM PQ, top), astrocytes derived from iPSCs (40 μM PQ, middle), and murine primary astrocytes from p16-3MR neonates (40 μM PQ, bottom), display obvious increase in SA-β-gal activity, but cell death occurred when human and mouse astrocytes were exposed to higher concentrations of PQ (500 and 250 μM, respectively).
fibroblast senescence (>500 μM PQ) was lethal to astrocytes (Figure 3D).

Epidemiological data suggest that, although the risk for developing PD is significant following a short-term (<8 day) environmental exposure to PQ, PD is even more significantly linked with chronic/low-dose PQ exposure (Tanner et al., 2011). We asked whether lower concentrations of PQ for a longer duration could induce senescence in human astrocytes. Cells exposed for 48 hr to 10 μM PQ showed a significant increase in SA-β-gal+ cells, and a 48-hr exposure to 50 μM PQ was nearly as effective as a 24-hr exposure to 100 μM PQ (Figure 4A). All exposures and concentrations reduced cell numbers compared to vehicle-treated cells consistent with proliferative arrest (Figure 4B). Lower more sustained PQ doses increased the percentage of senescent astrocytes to a similar or greater extent than exposure to H2O2 (150 mM for 2 hr) or the proteasomal inhibitor MG132 (50 nM for 48 hr) (Figure 4A), which are stress conditions reported to induce senescence of cultured human astrocytes (Bitto et al., 2010).

Soluble Factors Secreted by Senescent Human Astrocytes Compromise the Function of Neurons and Neural Progenitor Cells

Senescent cells can exert powerful paracrine effects on tissue microenvironments (Coppé et al., 2010); SASP factors have been shown to disrupt tissue structure and function (Brkic et al., 2015). We asked whether PQ-induced senescent astrocytes could drive PD-related neuropathologies associated with the neurotoxin, including DAergic neuronal cell death (Blesa and Przedborski, 2014) and reduced neural progenitor cell (NPC) proliferation and migration (Marxreiter et al., 2013). We cultured human DAergic neurons and NPCs in the presence of conditioned media (CM) from human astrocytes. CM from PQ-induced senescent astrocytes, but not non-senescent (vehicle-treated) astrocytes, significantly reduced the viability of DAergic neurons (Figure 5A). Similarly, CM from senescent astrocytes suppressed both NPC proliferation (Figure 5B) and migration (Figure 5C).

IL-6 is a prominent SASP factor, and elevated serum levels are associated with increased PD risk (Scalzo et al., 2010). Treating cultured DAergic neurons with recombinant IL-6 at the concentration found in the CM of PQ-treated astrocytes (1.5 μM) showed a trend toward reducing DAergic cell viability, but the effect was not statistically significant (Figure S2). This finding suggests that although IL-6 may contribute to neurotoxic SASP effects, additional factors are likely needed to mediate the detrimental impact on DAergic viability.

Depleting Senescent Cells Abrogates PQ-Induced Neuropathology

To test whether PQ-induced senescence contributes to neuropathologies in vivo, we used a mouse model that allows selective depletion of senescent cells (Demaria et al., 2014). These mice (p16-3MR) use the promoter for the senescence marker p16INK4a to drive expression of a modified herpes simplex virus thymidine kinase (HSV-TK), which converts the pro-drug ganciclovir (GCV) into a DNA chain terminator, causing cells to apoptose (Laberge et al., 2013). GCV eliminates 70%–80% of senescent cells in p16-3MR mice without discernible off-target or bystander effects (Demaria et al., 2014).

We subjected p16-3MR mice to a systemic PQ regimen shown to result in several neuropathological features of PD (McCormack and Di Monte, 2003; Shimizu et al., 2001). PQ increased nigrostriatal expression of p16INK4a and IL-6 (Figure 6A). As was the case for human astrocytes, PQ-treated p16-3MR astrocytes display increased SA-β-gal activity and were more sensitive to PQ-induced toxicity. Similar to astrocytes in human PD tissues, astrocytes from PQ-treated mice also displayed significant loss of nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013). Similar to our findings in the human PD SNpc, PQ did not significantly reduce nuclear lamin B1 and HMGB1 (high mobility group box 1), the latter necessary for SASP initiation (Figures 6B and 6C) (Davalos et al., 2013).
SNpc, PQ caused a significant decline in a marker of DAergic neurons, tyrosine hydroxylase (TH); co-administration of GCV with PQ prevented this decline (Figure 7A). Systemic PQ administration is known to repress adult neurogenesis, but co-GCV administration abrogated this effect (Figure 7B) (Markreiter et al., 2013). Finally, rearing behavior, a measure of motor neuron function more sensitive to DAergic cell loss than other motor tests (Willard et al., 2015), was significantly curbed in mice treated with PQ alone but normal in mice co-treated with GCV (Figure 7C). Taken together, these results suggest that senescent cell depletion abrogates PQ-mediated neuropathology and motor deficits.

**DISCUSSION**

Late-onset idiopathic PD is thought to result from the combined effects of genetic risk factors, aging, and environmental exposure. Data from several laboratories suggest that humans and animals exposed to certain chemicals can develop neuropathological phenotypes associated with PD (Chinta et al., 2008; McCormack et al., 2005; Peng et al., 2010). One of the best studied of these is PQ. A meta-analysis of >100 epidemiological studies concluded that of several specific pesticides and chemical classes evaluated, only PQ was significantly associated with PD. Moreover, as this study points out, the epidemiologic data are backed by numerous animal studies demonstrating that PQ selectively depletes SNpc DAergic neurons and reduces motor function in adult mice, which are important hallmarks of human PD (Pezzoli and Cereda, 2013).

PQ is a free radical generator that causes oxidative stress (Bus and Gibson, 1984), which has been demonstrated to induce cellular senescence in replication-competent cell types (Campisi, 2013). PQ also results in compromised mitochondrial function, which has recently been tied to senescence induction in human fibroblasts (Wiley et al., 2016). One mechanism by which PQ may contribute to PD is by inducing cellular senescence within the brain (Chinta et al., 2013). Indeed, PQ induced senescence more readily in cultured human and murine astrocytes than in human fibroblasts, and their sensitivity was found to track with baseline SA-β-gal activity. Our studies suggest that PQ, like other inducers of senescence (Park et al., 2013), has a bandwidth of concentrations that induce senescence; above an upper limit, cells die. This finding raises the possibility that astrocytes are particularly prone to undergo senescence in response to chronic low-dose exposure to PQ that is associated with late-onset idiopathic PD. Indeed, administration of PQ to mice appears to preferentially increase senescent markers in astrocytes. Importantly, senescence markers were also elevated in astrocytes in SNpc tissues from autopsied PD brain samples, suggesting that the proclivity for astrocytes to undergo senescence may have physiological disease relevance. To our knowledge, this is the first report of elevated senescent markers in the PD brain.

While our data suggest that senescence occurs preferentially within astrocytes, this does not rule out senescence induction of other brain cell types. While neurons are post-mitotic and therefore unlikely to undergo traditional senescence induction, senescence has reported in other non-astrocytic cell types. For example, in response to repeated lipopolysaccharide administration, microglial BV2 cells display growth arrest, enhanced SA-β-gal activity, and heterochromatic foci (Yum et al., 2012). Based on our own findings that PQ can mediate senescence in disparate cell types (astrocytes and fibroblasts), we anticipate that at some concentrations PQ may induce senescence of other replicative brain cell types.

It is theoretically possible that senescence induction in peripheral tissues could contribute to PQ-mediated brain pathologies, but this seems unlikely, as the chronic, low-dose PQ regimen utilized in our studies is known to result in receptor-mediated uptake and immune response in the brain (McCormack and Di Monte, 2003) without activating peripheral immune cells or disrupting blood-brain barrier integrity (Vilas-Boas et al., 2014; Watson et al., 2013).

How might senescent astrocytes contribute to PD neuropathology? Mature astrocytes rarely divide in the adult brain (Ge
et al., 2012; Sohn et al., 2015), consistent with our inability to detect Ki67+ astrocytes in the adult mouse brain; however, astrocytes do divide in response to certain injury (Barreto et al., 2011) and disease states (Boekhoorn et al., 2006; Bondolfi et al., 2002). The inability of senescent astrocytes to proliferate may exacerbate neuropathology when proliferation is an appropriate response to injury or disease. Astrocytes provide structural, metabolic, and trophic support to neurons (Allaman et al., 2011). When astrocytes adopt pro-inflammatory phenotypes, they can compromise neuronal function and contribute to age-related neurodegeneration and decrements in brain function in vivo (Rossi, 2015; Salminen et al., 2011). Factors secreted by senescent astrocytes had detrimental effects on both cultured human DAergic neurons and NPCs. CM from senescent astrocytes was supplemented with growth factors; therefore, trophic factor depletion seems an unlikely explanation. Secretion of IL-6 by cultured senescent human astrocytes was recently reported to decrease the viability of co-cultured motor neurons (Turnquist et al., 2016). We observed a similar increase in IL-6 secretion following PQ treatment in culture or in vivo, but IL-6 alone was not sufficient to induce significant degeneration of cultured DAergic neurons, suggesting that additional SASP factors may be required.

Why do DAergic SNpc neurons selectively degenerate in response to PQ and in PD? This is a pressing question in the field that our study does not explicitly address. However, we hypothesize that DAergic SNpc neurons may be particularly sensitive to the effects of oxidative stress on neighboring astrocytes, including senescence induction. In agreement with this idea, using an inducible astrocyte-specific oxidative stress mouse model, we previously demonstrated selective degeneration of DAergic SNpc neurons, despite astrocytes in other brain regions experiencing similar levels of oxidative stress (Mallajosyula et al., 2008).

In conclusion, our data show that astrocytes undergo cellular senescence in response to a well-established environmental stressor linked to PD and, significantly, that PQ-induced senescence contributes to PD-related neuropathology. This finding provides novel links among environmental exposure, cellular senescence, and PD. Further studies are warranted to identify other environmental and endogenous stressors capable of senescence induction in the brain. Our results suggest that senescent cells might be a novel therapeutic target for sporadic PD and other chronic neurodegenerative diseases in which environmental factors are implicated.

**EXPERIMENTAL PROCEDURES**

**PD Tissues and Ethics Statement**

Formalin-fixed paraffin-embedded SNpc sections were obtained from the Neurodegenerative Disease Research Brain Bank, University of Pennsylvania (U Penn) Center for Neurodegenerative Disease Research. Samples were collected from subjects aged 50–92 years at autopsy with previously diagnosed PD. Control samples were from age- and sex-matched subjects without PD. All samples were de-identified and obtained after approval by the U Penn institutional review board (protocol number 180600). A broker de-identified each specimen, no protected health information was made available to the researcher, and specimens were assigned numbers that could not be traced to the donors. There is no link between donor identifiers and the data; therefore, consent for this protocol was waived.
qPCR of Human Tissues and Cells

Total RNA was prepared from human SNpc or human-iPSC-derived cells using TRIzol (Invitrogen) and reverse transcribed using an Applied Biosystems kit (Carlsbad, CA). qRT-PCR was performed using the Universal Probe Library system (Roche, South San Francisco, CA) with the following primers and probes:

\[
p16^{INK4a}: \text{forward (FW)} 5'-gagcacatggagcttc-3'; \text{reverse (RV)} 5'-ctgaaccttgctgtg-3' \\
IL-6: \text{FW} 5'-gcgccagatctctccct-3'; \text{RV} 5'-gaagctgacagcacaac-3' \\
IL-1α: \text{FW} 5'-gggtgaatgqaaccaatca-3'; \text{RV} 5'-tgctgctagcggctatga-3' \\
IL-8: \text{FW} 5'-agacagcagacgacagaagc-3'; \text{RV} 5'-aggtcctgctgctgtg-3' \\
\text{MMP-3: FW} 5'-cacaactatctttcttgtagagcaca-3'; \text{RV} 5'-tcaagctttcgtgagaaa-3'.
\]

Immunofluorescence of Human SNpc Tissue

SNpc sections (6 μM) were rehydrated as follows: 2 x 7 min, xylene; 4 min each: 100%, 95%, 80%, and 70% ETOH; rinsed in DH2O; and washed in Tris-buffered saline (TBS), 10 min. Slides were then microwaved in 10 mM citrate buffer (pH 6.0) for 5 min at 40% power, cooled for 20 min, washed 10 min in TBS, and then blocked with 10% normal goat serum (NGS) in TBS + 0.05% Triton X-100 for 1 hr at room temperature. Sections were incubated at 4°C overnight with primary antibodies in blocking buffer (chicken TH: Novus, NB100-1613, 1:200 dilution; rat anti-rabbit-488: Life Technologies, A31566, 1:500 dilution; goat-anti rabbit-594: Life Technologies, A21102, 1:500 dilution; and GFAP-cy3: Life Technologies, A21103, 1:500 dilution). Slides were then washed three times in TBS followed by TBS, 0.025% TH: Novus, NB100-1613, 1:200 dilution; lamin B1: Abcam, ab16048, 1:200 dilution). Slides were washed three times in TBS and mounted with ProLong Gold plus DAPI (Life Technologies, P36934).

Lamin B1 Quantitation in Human SNpc Astrocytes

Immunostained sections were imaged with a Zeiss LSM 780 using an EC Plan-Neofluar 40X/1.30 oil Ph3 objective. 10X bright-field microscopy was used to locate GFAP+ cells in the vicinity of clustered pigmented neurons. A z stack spanning the cell body was acquired at 1,024 x 1,024 – 12 bit at 3X zoom using 1-μm steps. Fluorescence intensity was assessed using ImageJ. The optical section with the greatest green intensity (lamin B1) was identified. In the DAPI channel, the edge of the DAPI signal was outlined (defining the nuclear lamina), and the mean pixel value (MPV) on the green channel (lamin B1) was calculated; this signal was divided by a signal outside all nuclei in order to normalize for background staining and normalized fluorescence intensity averaged across 5 GFAP+ cells within a single section. Neighboring GFAP+ cells were chosen based on being closest and in the same Z section as the analyzed astrocyte. Significance was calculated using a paired t test per pair aging and sex-matched individuals from PD and control groups (n = 5 PD samples, 5 controls).

Treatment of Human Cultures

Human astrocytes derived from iPSCs purchased from XCell Science (Novato, CA) grown in astrocyte media were cultured at 37°C, 3% O2, and 5% CO2 in DMEM supplemented with 10% horse serum, 10% fetal bovine serum (FBS), and penicillin/streptomycin. Cells were seeded at 1 x 10⁴ cells/cm² and assessed for SA-β-gal staining as described previously (Dimri et al., 1995). Cells were treated with indicated PQ concentrations for 24 or 48 hr and washed twice with culture media; analyses were performed 7–8 days later.

BrdU Incorporation

Cell proliferation was determined by measuring DNA synthesis using a modified BrdU labeling kit (Roche). Cells were seeded in 4-well chamber slides and incubated with BrdU for 1 hr before washing and fixing with 4% paraformaldehyde. Fixed cells were washed with PBS and BrdU immunofluorescence quantified.

SA-β-gal Assay

SA-β-gal staining was performed as described previously (Dimri et al., 1995). Cells were plated at 1 x 10⁴ cells/cm² and assessed for SA-β-gal activity 24–48 hr after seeding in a minimum of 400 cells. Positive (blue) cells are expressed as a percentage of total cell number.

Immunofluorescence of Cultured Cells

Cells were fixed with 4% formaldehyde, permeabilized with 0.5% Triton, and blocked with 10% goat or donkey serum before incubating overnight with primary antibody at 4°C. After washing in PBS, cells were incubated with...
Alexa-conjugated secondary antibodies for 30–45 min at room temperature. Nuclear DNA was stained with DAPI in mounting media (Vectashield). CellProfiler image analysis software was used to score cells. Primary antibodies were anti-p16 (clone JCS: Santa Cruz Biotechnology, sc-56330, 1:200 dilution), anti-p53BP1 (clone BP13: EMD Millipore, MAB3802, 1:200 dilution), anti-lamin B1 (Abcam, ab16048, 1:200 dilution), and anti-Ki67 (Abcam, ab15580; 1:200 dilution). For the latter, image data were analyzed using CellProfiler to quantify the number of K67+ (% K67+) DAPI-stained nuclei. The mean pixel area of DAPI-stained nuclei was obtained for each condition (IR and PQ) and normalized to the mean pixel area of nuclei under control conditions (for relative nuclear size).

IL-6 ELISA
CM was prepared by washing cells three times in PBS followed by incubation in serum-free DMEM for 24 hr. CM was filtered and stored at ~80°C. Cell numbers were determined by counting. ELISAs were performed using the alphaLISA IL-6 Immunoassay Research kit (Perkin Elmer). Data were normalized to cell number and expressed as picograms per 1,000 cells.

Preparation of Primary 3MR Astrocytes
Primary cortical astrocytes were prepared as described previously (Schlidge et al., 2013). Cortices were dissected from post-natal day 2 mice and dissociated and plated, and cultured for 2 weeks with removal of microglia by orbital shaking prior to conducting experiments. Cells were treated with PQ as indicated and after 24 hr washed twice with culture media. SA-β-gal activity was assessed 8 days after PQ treatment as described above.

Viability of Human DAergic Neurons
Primary human DAergic neurons were obtained from Celprogen (San Pedro, CA) and cultured as instructed by the manufacturer. Cells were maintained in complete medium and subcultured every 24–48 hr on human dopamine neuronal primary cell culture extracellular matrix. Briefly, 1 x 10^5 cells were plated onto flat-bottomed 96-well plates. CM from astrocytes was concentrated using spin columns with a 10-kDa cutoff and reconstituted in Da-complete medium. After 24 hr, cells were exposed to CM astrocytic CM for 72 hr. Cells were treated with 50 μM MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl-tetrazolium-bromide) solution (5 mM/mg) for 3 hr at 37°C. 200 μL dimethyl sulfoxide (Sigma, USA) was added to each well and incubated for 30 min at 37°C. Color intensity was quantified at 570 nm. The experiment was run three times in 3 different sets of CM, and each condition was run in quadruplicate.

Derivation of Human NPCs
Human embryonic stem cell colonies were harvested after collagenase treatment, cultured as embryoid bodies for 8 days in DMEM with 20% FBS, and cultured in neural induction medium (DMEM/F12) N2 supplement (Invitrogen, 25 ng/mL basic fibroblast growth factor [bFGF]) for 7 days on plates coated with Geltrix. Rosettes were manually isolated, dissociated into single cells and expanded in neural expansion medium. NPCs were then incubated for 48 hr in astrocytic CM. Cell proliferation was determined using a modified BrdU labeling kit (Roche) as above.

Scratch Migration Assay
As described elsewhere (Liang et al., 2007), NPCs were cultured to confluence in 60-mm dishes. The monolayer was scraped with a p200 pipet tip to create a “scratch.” Debris was removed and astrocytic CM was added for 48 hr. Using phase contrast microscopy, images were acquired at 0, 24, and 48 hr after the scratch. The mean width of each scratch was calculated by averaging 6 width measurements taken at even intervals along the scratch length. The relative rate of migration was determined by calculating the percentage of scratch width invaded = 100% – (100% [mean width at t0] – mean width at t]). Quantification was carried out using ImageJ.

PQ Administration
p16-3MR mice were generated in the C57Bl/6J mouse strain as described previously (Demaria et al., 2014). Animals were housed according to standard animal care protocols on a 12-hr light/dark cycle in a pathogen-free environment in the vivarium at the Buck Institute. 8-month-old male and female mice were injected intraperitoneally (i.p.) with saline or 7 mg/kg PQ (in saline) at 2-day intervals for a total of 6 doses. GCV (25 mg/kg body weight) was injected i.p. after the second PQ injection and every other day for a total of 5 doses. Animals were sacrificed 7 d after the last PQ administration as described previously (Peng et al., 2010). Animal care and use were in accordance with the National Institutes of Health guidelines for use of live animals and approved by the Animal Care and Use Committee at the Buck Institute.

ePCR of Mouse Striatal Tissues
RNA from PQ- and saline-treated mice was reverse transcribed using an Applied Biosystems kit (Carlsbad CA). qRT-PCR reactions were performed using the following primers and probes:

Immunofluorescence of Mouse Brain Tissue
Whole brains were dissected and placed in cold 4% paraformaldehyde in PBS for 12 hr, washed in cold TBS, cut using a Leica VT 1000S Vibratome (collecting 50-μm horizontal sections in cryogenic buffer [0.1 M potassium acetate, 40% ethylene glycol, and 1% polyvinyl pyrrolidone]), and stored at ~20°C. Free-floating sections containing the SN were transferred to 1 mL unmasking buffer (10 mM Tris and 1 mM EDTA [pH 9]) in 24-well dishes and microwaved 3 x 5 at 100% power. Sections were washed in TBS, permeabilized in TBS plus 0.2% Triton X-100 for 1 hr, blocked in 5% normal goat serum in permeabilization buffer for 1 hr, and then bathed in blocking buffer at 4°C overnight with primary antibodies (chicken anti-TH with either rabbit anti-Lamin B1 or rabbit anti-HMGB1, Abcam, ab18256, 1:200). Section were washed three times with TBS plus 0.1% Tween-20 for 1 hr and bathed in TBS, 0.1% Tween-20, 5% NGS, and fluorescent-conjugated antibodies (goat anti-rabbit immunoglobulin G [IgG]-Alexa 488 at 1:500; goat anti-chicken IgG/Alexa 633 at 1:500, and GFAP-cy3 at 1:2,000). Primary and secondary antibodies are the same as those listed for human IF. Sections were washed three times with TBS plus 0.1% Tween-20 for 2 hr before mounting on glass slides with ProLong Gold plus DAPI.

Analysis of Lamin B1 and HMGB1 in Mouse SNpc Astrocytes
Image acquisition and analysis of Lamin B1 and HMGB1 immunostaining in mouse astrocytes was conducted similar to that described for human brain tissues, except GFAP+ cells were chosen in fields containing TH staining. For HMGB1 analysis, the region of interest was drawn in the center of DAPI signal (in the nucleoplasm). Signals were calculated by averaging fluorescence from 5 astrocytes per section and subsequently averaging 3 sections per animal. Significance was calculated using non-paired t test with n = 4 animals in each condition.

Stereological SN TH+ Counts
Mouse tissues were fixed by perfusion as described and cryostat-cut sections (40 μm) were taken through the entire midbrain (Mallajosyula et al., 2008). TH+ neurons were immune-labeled by incubating the sections successively with a rabbit polyclonal anti-TH antibody (1:200) and biotinylated horse anti-rabbit IgG (1:200, Vector Laboratories) in combination with 3,3′-diaminobenzidine (DAB) reagents. Total # TH+ SNpc neurons were counted from 4 to 5 littermates per group using the optical fractionator method (Peng et al., 2010).

Cylinder Test of Motor Behavior
Mice were placed individually in a cylinder to determine the number of rearing events over 1 min (Willard et al., 2015). Each rearing session was video recorded. The average number of rears over two trials was taken.

In Vivo BrdU Labeling and Quantitation
BrdU (50 mg/kg; Sigma) in saline was given i.p. two times daily at 8-hr intervals on consecutive days (days 1–3 after PQ or saline administration). Mice were
coated slides with Fluoromount. SVZ BrdU+ cells were counted blinded in

Statistical Methods
For experiments using post-mortem human tissues (Figure 1), n represents individuals; for all experiments using cultured cells (Figures 2, 3, 4, and 5), n represents experimental replicates conducted on separate days; and for all mouse studies (Figures 6 and 7), n represents individual mice. See figure legends for exact numbers for each individual experiment. All error bars in figures display SEM. Results were reported as significant when p values were <0.05, running an unpaired Student’s t test, unless noted otherwise in figure legends.

SUPPLEMENTAL INFORMATION
Supplemental Information includes Supplemental Experimental Procedures and three figures and can be found with this article online at https://doi.org/10.1016/j.celrep.2017.12.092.

ACKNOWLEDGMENTS
We thank Dr. John Trojanowski for providing materials from the University of Pennsylvania Brain Bank and Chris Lieu for assistance with behavioral studies. This work was funded by an Ellison Senior Scholar in Aging Award AG-SS-2620-11 (J.K.A.), Buck Impact circle (J.K.A and J.C), Michael J Fox Foundation, Target validation grant MUF-12113 (J.K.A), NIH grant AG009909 (J.C.), an NIH Institutional Postdoctoral Training Grant T32-AG000266 (G.W.), a CIRM training grant TG2-01155 (S.J.C.), and the American-Italian Cancer Foundation (M.D.).

AUTHOR CONTRIBUTIONS
S.J.C., G.W., J.K.A., and J.C. conceived the experiments and wrote the paper. S.J.C. and G.W., with the help of M.D., A.R., Y.Z., A.M., S.R., C.L., and D.T.M., conducted experiments and gathered data. S.J.C. and G.W. analyzed the data and prepared the figures.

DECLARATION OF INTERESTS
J.C. a scientific founder of Unity Biotechnology, which is developing “seno-
lytics” therapies for age-related pathologies. She owns shares in Unity but does not receive consulting fees. Unity supports basic research in her laboratory, but not the research described in this publication. The remaining authors declare no competing interests.
